abstract

Herpes simplex virus (HSV) infection of the neonate is uncommon, but genital herpes infections in adults are very common. Thus, although treating an infant with neonatal herpes is a relatively rare occurrence, managing infants potentially exposed to HSV at the time of delivery occurs more frequently. The risk of transmitting HSV to an infant during delivery is determined in part by the mother’s previous immunity to HSV. Women with primary genital HSV infections who are shedding HSV at delivery are 10 to 30 times more likely to transmit the virus to their newborn infants than are women with recurrent HSV infection who are shedding virus at delivery. With the availability of commercial serological tests that reliably can distinguish type-specific HSV antibodies, it is now possible to determine the type of maternal infection and, thus, further refine management of infants delivered to women who have active genital HSV lesions. The management algorithm presented herein uses both serological and virological studies to determine the risk of HSV transmission to the neonate who is delivered to a mother with active herpetic genital lesions and tailors management accordingly. The algorithm does not address the approach to asymptomatic neonates delivered to women with a history of genital herpes but no active lesions at delivery. Pediatrics 2013;131:e635–e646

INTRODUCTION

Herpes simplex virus (HSV) infection of the neonate is an uncommon occurrence, with an estimated 1500 cases diagnosed annually in the United States from a birth cohort of more than 4 000 000. In contrast, genital herpes infections in adults are very common. Between 1 in 4 and 1 in 5 adults in the United States has genital herpes caused by HSV type 2 (HSV-2).1,2 In addition, HSV type 1 (HSV-1) now accounts for at least 20% and, in some locales, more than 50% of cases of genital herpes in the United States.3,4 Therefore, managing infants potentially exposed to HSV at the time of delivery is not uncommon, and prevention of the devastating outcomes of neonatal HSV disease is paramount.

Current recommendations for the management of infants after intrapartum exposure are based on expert opinion, because a randomized controlled trial to determine whether an exposed neonate should be treated would be unethical. However, the existing recommendations do
not take into account recent information correlating risk of transmission with type of maternal infection (primary versus recurrent) at the time of delivery. The algorithm contained within this American Academy of Pediatrics (AAP) clinical report for the diagnostic and therapeutic approach to the neonate with known potential exposure to HSV during the perinatal period incorporates the most current scientific understanding of the biology, epidemiology, and pathology of HSV infection and disease.

**TERMINOLOGY OF HSV INFECTION AND DISEASE**

When an individual with no HSV-1 or HSV-2 antibody acquires either virus in the genital tract, a first-episode primary infection results. If a person with pre-existing HSV-1 antibody acquires HSV-2 infection results. If a person with pre-existing HSV-1 antibody acquires either virus in the genital tract, a first-episode nonprimary infection ensues. Viral reactivation from latency and subsequent antegrade translocation of virus back to skin and mucosal surfaces produces a recurrent infection.

Genital HSV infection can be either clinically apparent (eg, genital lesions) or inapparent (asymptomatic, or subclinical). Transmission to the neonate at the time of birth can occur with either presentation.

The distinction between neonatal HSV infection and neonatal HSV disease warrants discussion. Infection occurs when viral replication has been established, but the virus is not causing illness. Disease occurs when viral replication produces clinical signs of illness (eg, skin lesions, encephalitis, hepatitis). Once an infant is infected with HSV, progression to neonatal HSV disease is virtually certain. In an effort to prevent this progression from neonatal infection to neonatal disease, experts have recommended for many years that parenteral acyclovir be administered preemptively to HSV-infected neonates.

**RISK OF MATERNAL INFECTION DURING PREGNANCY**

Recurrent infections are the most common form of genital HSV during pregnancy. Approximately 10% of HSV-2-seronegative pregnant women have an HSV-2-seropositive sexual partner and, thus, are at risk for contracting a primary HSV-2 infection during the pregnancy and transmitting the virus to their infants during delivery. Approximately one-fifth to one-third of women of childbearing age are seronegative for both HSV-1 and HSV-2 and, among discordant couples, the chance that a woman will acquire either virus during pregnancy is estimated to be 3.7%. For women who are already seropositive for HSV-1, the estimated chance of HSV-2 acquisition during the pregnancy is 1.7%. Approximately two-thirds of women who acquire genital herpes during pregnancy remain asymptomatic and have no symptoms to suggest a genital HSV infection.

This is consistent with the finding that 60% to 80% of women who deliver an HSV-infected infant have a clinically unapparent genital HSV infection at the time of delivery and have neither a past history of genital herpes nor a sexual partner reporting a history of genital HSV.

**RISK OF NEONATAL HSV INFECTION**

HSV infection of the newborn infant is acquired during 1 of 3 distinct times: intrauterine (in utero), intrapartum (perinatal), and postpartum (postnatal). The time of transmission of HSV-1 or HSV-2 for the overwhelming majority of infected infants (~85%) is in the intrapartum period. An additional 10% of infected neonates acquire HSV-1 postnatally from either a maternal or nonmaternal source, and the final 5% are infected with HSV-2 or HSV-1 in utero. Five factors known to influence transmission of HSV from mother to neonate are:

1. Type of maternal infection (primary versus recurrent)
2. Maternal HSV antibody status
3. Duration of rupture of membranes
4. Integrity of mucocutaneous barriers (eg, use of fetal scalp electrodes)
5. Mode of delivery (cesarean versus vaginal delivery)

Infants born to mothers who have a first episode of genital HSV infection near term and are shedding virus at delivery are at much greater risk of developing neonatal herpes than are infants whose mothers have recurrent genital herpes.

The largest assessment of the influence of type of maternal infection on likelihood of neonatal transmission is a landmark study involving almost 60,000 women in labor who did not have clinical evidence of genital HSV disease, approximately 40,000 of whom had cultures performed within 48 hours of delivery. Of these, 121 women were identified who were asymptotically shedding HSV and who had sera available for analysis. In this large trial, 57% of infants delivered to women with first-episode primary HSV infection developed neonatal HSV disease, compared with 25% of infants delivered to women with first-episode nonprimary infection and 2% of infants delivered to women with recurrent HSV disease.

**CLINICAL MANIFESTATIONS OF NEONATAL HSV DISEASE**

HSV infections acquired either intrapartum or postpartum can be classified as: (1) disease involving multiple visceral organs, including lung, liver, adrenal glands, skin, eye, and/or brain (disseminated disease); (2) central nervous system (CNS) disease, with or without skin lesions (CNS disease); and (3) disease limited to the skin, eyes, and/or mouth (skin, eye, mouth (SEM)
disease). This classification system is predictive of both morbidity and mortality.23–27 Neonates with disseminated and SEM HSV disease typically present for medical attention at 10 to 12 days of age, whereas infants with CNS disease typically present at 17 to 19 days of age.24 Overall, approximately half of all infants with neonatal HSV disease will have CNS involvement (CNS disease or disseminated disease with CNS involvement), and approximately 70% will have characteristic vesicular skin lesions (SEM disease, 83%; CNS disease, 63%; disseminated disease, 58%).24

**DIAGNOSIS OF GENITAL HSV DISEASE**

HSV can be detected from genital lesions by polymerase chain reaction (PCR) assay, viral culture, or antigen detection. Of these, PCR assay or viral culture are the testing modalities recommended by the Centers for Disease Control and Prevention for the diagnosis of genital HSV lesions.28 The sensitivity of viral culture from genital lesions is low, especially for recurrent infection, and declines rapidly as lesions begin to heal. PCR assays for HSV DNA are more sensitive and are increasingly used for the diagnosis of genital HSV.28,29 A potential limitation of the PCR assay at the current time relates to its availability in all clinical settings; some smaller or more remote medical facilities have limited or no access to laboratories offering this technology. At many tertiary care centers, PCR assay results may be available within a day, whereas it takes 2 to 5 days for HSV to grow in viral culture. Typing of an HSV culture isolate or PCR assay product to determine if it is HSV-1 or HSV-2 can be accomplished by one of several techniques. The reliability of viral culture depends on the stage of the episode, with higher quantities of virus being present during the prodromal and vesicular stages than during crusting.30 Antigen detection methods are available commercially but may not distinguish HSV-1 from HSV-2 and are not recommended by the Centers for Disease Control and Prevention for the diagnosis of genital herpes.

Before the year 2000, commercially available serological assays were unable to distinguish between HSV-1 and HSV-2 antibodies, severely limiting their utility. Over the past decade, a number of type-specific serological assays that reliably distinguish between immunoglobulin G (IgG) directed against HSV-1 and HSV-2 have been approved by the US Food and Drug Administration (Table 1). Many of these products are sold in kits that are used by clinical laboratories throughout the United States. Several additional tests that claim to distinguish between HSV-1 and HSV-2 antibody are available commercially, but high cross-reactivity rates attributable to their use of crude antigen preparations limit their utility,51 and their use is not recommended.

**DIAGNOSIS OF NEONATAL HSV DISEASE**

Isolation of HSV by culture remains the definitive diagnostic method of establishing neonatal HSV disease. If skin lesions are present, a scraping of the vesicles should be transferred in appropriate viral transport media on ice to a diagnostic virology laboratory.6 Other sites from which specimens should be obtained for culture of HSV include the conjunctivae, mouth, nasopharynx, and rectum (“surface cultures”).6 Specimens for viral culture from mucosal body sites may be combined before inoculating in cell culture to decrease costs, because the important information gathered from such cultures is the presence or absence of replicating virus rather than its precise body site. The sensitivity of PCR assay on surface specimens has not been studied; if used, surface PCR assay should be performed in addition to (and not instead of) the gold-standard surface culture. Rapid diagnostic techniques also are available, such as direct fluorescent antibody staining of vesicle scrapings or enzyme immunoassay detection of HSV antigens. These techniques are as specific but slightly less sensitive than culture.

The diagnosis of neonatal HSV CNS disease has been greatly enhanced by PCR testing of cerebrospinal fluid (CSF) specimens,52–58 and PCR assay is now the method of choice for documenting CNS involvement in an infant
suspected of having HSV disease. However, PCR assay of CSF should only be performed in conjunction with HSV surface cultures, given that up to 40% of infants with disseminated disease will not have CNS involvement, and, by definition, no infants with SEM disease will have CNS involvement. PCR analysis of CSF also should play a role in determining the duration of antiviral therapy, because available data suggest that having HSV DNA detected in CSF at or after completion of intravenous therapy is associated with poor outcomes. All infants with a positive CSF PCR assay result for HSV anti-HSV DNA at the beginning of antiviral therapy should have a repeat lumbar puncture near the end of treatment to determine if HSV DNA has been cleared from the CNS. Infants whose PCR assay result remains positive should continue to receive intravenous antiviral therapy until the CSF PCR assay result is negative. The sensitivity of CSF PCR testing in neonatal HSV disease ranges from 75% to 100%.33,36,38

Application of PCR testing to blood specimens from infants with suspected HSV disease appears promising.32-37 All infants with positive CSF PCR assay results for HSV anti-HSV DNA at the beginning of antiviral therapy should have a repeat lumbar puncture near the end of treatment to determine if HSV DNA has been cleared from the CNS. Infants whose PCR assay result remains positive should continue to receive intravenous antiviral therapy until the CSF PCR assay result is negative. The sensitivity of CSF PCR testing in neonatal HSV disease ranges from 75% to 100%.33,36,38

Serological testing is not helpful in the diagnosis of neonatal HSV infection, because transplacentally acquired maternal HSV IgG is present in most infants born to HSV-1 and/or HSV-2 seropositive adult American population who are HSV-viremic. Because HSV-2 is present in most infants born to HSV-1 and/or HSV-2 seropositive adult American population who are HSV-viremic, the duration of neonatal HSV infection in the newborn is not as long as that of HSV-1 infection. The duration of neonatal HSV infection is not helpful in the diagnosis of neonatal HSV disease. Serological testing of neonatal HSV disease appears promising.32-37 All infants with positive CSF PCR assay results for HSV anti-HSV DNA at the beginning of antiviral therapy should have a repeat lumbar puncture near the end of treatment to determine if HSV DNA has been cleared from the CNS. Infants whose PCR assay result remains positive should continue to receive intravenous antiviral therapy until the CSF PCR assay result is negative. The sensitivity of CSF PCR testing in neonatal HSV disease ranges from 75% to 100%.33,36,38

shading HSV at delivery are 10 to 30 times more likely to transmit the virus to their newborn infants than women with a recurrent infection.\textsuperscript{5} The increased risk is attributable both to lower concentrations of transplacental HSV-specific antibodies (which also are less reactive to expressed polypeptides) in women with primary infection\textsuperscript{19} and to the higher quantities of HSV that are shed for a longer period of time in the maternal genital tract in comparison with women who have recurrent genital HSV infection.\textsuperscript{54} However, a substantial percentage of women with first clinical episodes of symptomatic genital herpes actually are experiencing reactivation of a previously unrecognized genital herpetic infection.\textsuperscript{55} Thus, to tailor management of exposed neonates according to their degree of risk, one must distinguish primary versus recurrent maternal HSV infection in a manner that relies on more than just the history, or lack thereof, of genital herpes in the woman or her partner (s). Ideally, detection of HSV DNA from genital swabs obtained from women in labor would identify both symptomatic and asymptomatic HSV shedding, allowing for focused management of only those infants who are exposed; however, the technology to accomplish this on a broad scale is not readily available commercially at this time.

With the approval of commercially available serological tests that can reliably distinguish type-specific HSV antibodies (Table 1), the means to further refine management of asymptomatic neonates delivered to women with active genital HSV lesions is now possible. The algorithm detailed in Figs 2 and 3 applies only to asymptomatic neonates after vaginal or cesarean (because cesarean delivery reduces but does not eliminate the risk of neonatal HSV disease) delivery to women with active genital HSV lesions. It is intended to outline 1 approach to the management of these infants and may not be feasible in settings with limited access to PCR assays for HSV DNA or to the newer type-specific serological tests. If, at any point during the evaluation outlined in the algorithm, an infant develops symptoms that could possibly indicate neonatal HSV disease (fever, hypothermia, lethargy, irritability, vesicular rash, seizures, etc), a full diagnostic evaluation should be undertaken, and intravenous acyclovir therapy should be initiated. In applying this algorithm, obstetric providers and pediatricians likely will need to work closely with their diagnostic laboratories to ensure that serological and virological testing is available and turnaround times are acceptable. In situations in which this is not possible, the approach detailed in the algorithm will have limited, and perhaps no, applicability.

**Algorithm for Management of Asymptomatic Neonates Born Vaginally or by Cesarean Delivery to Women With Active Genital HSV Lesions (Figs 2 and 3)**

The risk of transmitting HSV to the newborn infant during delivery is influenced directly by the mother’s previous immunity to HSV; women who have primary genital HSV infections who are

1999, the American College of Obstetricians and Gynecologists updated its management guidelines for genital herpes in pregnancy.\textsuperscript{43} To reduce the risk of neonatal HSV disease, cesarean delivery should be performed if genital HSV lesions or prodromal symptoms are present at the time of delivery. Neonatal HSV infection has occurred despite cesarean delivery performed before the rupture of membranes.\textsuperscript{12,44}

In women with a previous diagnosis of genital herpes, cesarean delivery to prevent neonatal HSV infection is not indicated if there are no genital lesions at the time of labor. In an effort to reduce cesarean deliveries performed for the indication of genital herpes, the use of oral acyclovir or valacyclovir near the end of pregnancy decreases the occurrence of clinically apparent genital HSV disease at the time of delivery.\textsuperscript{45–48} with an associated decrease in cesarean delivery rates for the indication of genital HSV.\textsuperscript{45,46,49,50} However, because viral shedding still occurs (albeit with reduced frequency),\textsuperscript{47,51} the potential for neonatal infection is not avoided completely, and cases of neonatal HSV disease in newborn infants of women who were receiving antiviral suppression recently have been reported.\textsuperscript{52,53}

**Testing of Women in Labor**

Women in labor with visible genital lesions that are characteristic of HSV should have the lesions swabbed for HSV PCR and culture (AI). Any positive test result then requires further analysis to determine if the virus is HSV-1 or HSV-2. Correlation of viral type with serological status allows for determination of maternal infection classification (Table 2).

**Management of Asymptomatic Neonates After Vaginal or Cesarean Delivery to Women With Lesions at Delivery and History of Genital HSV Preceding Pregnancy**

For women with a history of genital herpes preceding the pregnancy, the likelihood that the current outbreak represents reactivation of latent HSV is high, and, therefore, the likelihood of transmission to the infant is low (2%). Skin and mucosal specimens (conjunctivae, mouth, nasopharynx, and rectum, and scalp electrode site, if present) should be obtained from the...
neonate for culture (and PCR assay, if desired) at approximately 24 hours after delivery (BII), and blood should be sent for HSV DNA PCR assay. Acyclovir need not be started as long as the infant remains asymptomatic (BIII).

The importance of waiting until approximately 24 hours after delivery to obtain virological studies is based on the fact that a positive virological test result at that point represents actively replicating virus on the infant’s mucosa, whereas a positive test result shortly after birth could reflect only transient maternal contamination that may not lead to replication with resulting neonatal HSV disease.56 It is permissible to discharge an asymptomatic infant after

FIGURE 2
Algorithm for the evaluation of asymptomatic neonates after vaginal or cesarean delivery to women with active genital herpes lesions. ALT, alanine aminotransferase; D/C, discontinue.
48 hours of negative HSV cultures (and negative PCR assay results) if other discharge criteria have been met, there is ready access to medical care, and a person who is able to comply fully with instructions for home observation will be present (BIII). If any of these conditions is not met, the infant should be observed in the hospital until HSV cultures are finalized as negative or are negative for 96 hours after being set up in cell culture, whichever is shorter.

If the surface and blood virological study results are negative at 5 days, the infant should be evaluated if signs or symptoms of neonatal HSV disease develop during the first 6 weeks of life (AII). Conversely, if the surface and blood virological study results become positive, thus confirming neonatal HSV infection, the infant should undergo a complete evaluation (lumbar puncture with CSF sent for indices and HSV DNA PCR assay, in addition to serum alanine transaminase) to determine the extent of disease, and intravenous acyclovir should be initiated as soon as possible. If the evaluation findings are normal, indicating that the neonate has HSV infection but that it has not yet progressed to HSV disease, the infant should be treated empirically with intravenous acyclovir for 10 days to prevent progression from infection to disease (preemptive therapy) (BIII). If the evaluation findings are abnormal, the infant should be treated with intravenous acyclovir for 10 days to prevent progression from infection to disease (preemptive therapy) (BIII).
indicating the neonate already has neonatal HSV disease, the infant should be treated for 14 to 21 days with intravenous acyclovir on the basis of the extent of neonatal HSV disease (disseminated, CNS, or SEM) (AII); if the initial CSF PCR assay result is positive for HSV DNA, a repeat lumbar puncture should be obtained near the end of therapy (eg, on day 17 or 18 of an anticipated 21-day course of therapy), and intravenous acyclovir should be discontinued at 21 days if the repeat HSV PCR assay result is negative (AII). If the “end-of-therapy” CSF PCR assay result is positive, intravenous acyclovir should be continued for another 7 days, with another repeat lumbar puncture near the end of therapy, again with decisions regarding cessation of therapy predicated on the repeat HSV CSF PCR assay result (BII). After completion of parenteral acyclovir for treatment of neonatal HSV disease, infants should receive oral acyclovir suppressive therapy for 6 months.57

Management of Asymptomatic Neonates After Vaginal or Cesarean Delivery to Women With Lesions at Delivery and No History of Genital HSV Preceding Pregnancy

For women without a history of genital herpes preceding pregnancy, the presence of genital lesions at delivery could represent first-episode primary infection (with a risk of transmission to the newborn infant of 57%), first-episode nonprimary infection (with a risk of transmission to the newborn infant of 25%), or recurrent infection (with a risk of transmission to the newborn infant of 2%). Thus, with the availability of type-specific serological testing, the practitioner can determine which type of infection the outbreak represents, given that the risks to the infant are so disparate. Accordingly, serological testing should be performed to determine the type of HSV infection in the mother to delineate between the 3 (Table 1).

At approximately 24 hours after delivery, neonatal skin and mucosal specimens (conjunctivae, mouth, nasopharynx, and rectum, and scalp electrode site, if present) should be obtained for culture (and PCR assay, if desired), and blood should be sent for HSV DNA PCR assay to evaluate for HSV infection. In addition, the infant should be evaluated for neonatal HSV disease (lumbar puncture with CSF sent for indices and HSV DNA PCR assay, in addition to serum alanine transaminase) at the same time, and intravenous acyclovir should be initiated pending the results of the evaluation, because the possibility is high that this could be a primary maternal infection (BII). It is acceptable to wait to initiate therapy until approximately 24 hours after delivery in an asymptomatic neonate, because the average age at onset of neonatal HSV disease is between 1.5 and 3 weeks of age. Some practitioners advocate evaluation and treatment immediately after delivery if the infant is preterm or there has been prolonged rupture of membranes (CIII).

Laboratory correlations between virological (PCR/culture) and serological results that define maternal disease classification (first-episode primary, first-episode nonprimary, and recurrent) are presented in Table 2. The table deliberately uses a conservative estimate of first-episode infection, because the likelihood of transmission in such a situation is high. It is intended to be used to determine maternal disease classification in women without a clinical history of genital herpes.

If the mother has a documented or assumed first-episode primary or first-episode nonprimary infection (Table 2) and the neonate’s evaluation results are normal, the infant should be treated empirically with intravenous acyclovir for 10 days to prevent progression from neonatal infection to disease (preemptive therapy) (BIII). If the infant’s evaluation results are abnormal, indicating the neonate already has neonatal HSV disease, the infant should be treated for 14 to 21 days with intravenous acyclovir on the basis of the extent of neonatal HSV disease (disseminated, CNS, or SEM) (AII); if the initial CSF PCR assay results are positive for HSV DNA, a repeat lumbar puncture should be obtained near the anticipated end of therapy (eg, on day 17 or 18 of therapy), and intravenous acyclovir should be discontinued at 21 days if the repeat HSV PCR assay result is negative (AII). If the end-of-therapy CSF PCR assay result is positive, the intravenous acyclovir should be continued for another 7 days, with another repeat lumbar puncture near the anticipated new end of therapy, again with decisions regarding cessation of therapy predicated on the HSV CSF PCR assay result (BII). After completion of parenteral acyclovir for treatment of neonatal HSV disease, infants should receive oral acyclovir suppressive therapy for 6 months.57

If the mother has recurrent genital HSV infection (that is, she has type-specific antibody to the HSV serotype detected by her genital swab) and the neonatal surface and blood virology study results are negative, acyclovir should be stopped, the parent(s) should receive education regarding signs and symptoms of neonatal HSV, and the infant may be discharged and reevaluated with any signs or symptoms of illness during the first 6 weeks of life (AII). Conversely, if virology study results are positive, confirming neonatal HSV infection, intravenous acyclovir should be continued, with the duration of treatment based on the evaluation for neonatal HSV disease. If the evaluation findings are normal, the infant should be treated empirically with intravenous acyclovir for 10 days to prevent progression from HSV...
infection to HSV disease (preemptive therapy) (BIII). If the evaluation findings are abnormal, the infant should be treated with intravenous acyclovir for 14 to 21 days on the basis of the extent of neonatal HSV disease (disseminated, CNS, or SEM) (AII); if the initial CSF PCR assay result is positive for HSV DNA, a repeat lumbar puncture should be obtained near the end of therapy (eg, on day 17 or 18 of an anticipated 21-day course of therapy), and intravenous acyclovir should be discontinued at 21 days if the repeat HSV PCR assay result is negative (AII). If the end-of-therapy CSF PCR assay result is positive, intravenous acyclovir should be continued for another 7 days, with another repeat lumbar puncture near the end of therapy, again with decisions regarding cessation of therapy predicated on the basis of HSV CSF PCR assay result (BII). After completion of parenteral acyclovir for treatment of neonatal HSV disease, infants should receive oral acyclovir suppressive therapy for 6 months.57
